

Scenarios for the European Securities and Market Authority's EU-wide central counterparty stress test in 2017

Introduction

In accordance with its mandate, the European Securities and Markets Authority (ESMA), in cooperation with the ESRB, initiates and coordinates EU-wide stress tests to assess the resilience of central counterparties (CCPs) to adverse market developments. ESMA plans to conduct a stress test for central counterparties in 2017 and has requested adverse financial scenarios and measures of probability of default for clearing members. The ECB, in collaboration with the ESRB, has developed a methodology and calibrated adverse financial scenarios for this exercise. This document sets out these scenarios and provides details on the methodology used for their calibration.¹ It has been approved by the ESRB General Board and transmitted to ESMA.

The shock profiles for the individual risk factors presented in this document should be interpreted as one-off, instantaneous shifts in asset prices relative to their mid-September 2016 levels. Each scenario includes more than 500 individual risk factors, reflecting the variety of products cleared by European CCPs. Annex A presents the methodology used for calibrating the scenarios. Annex B presents the three scenarios, with shocks originating in the credit default swap (CDS), foreign exchange (FX) and money markets. Annex C describes the methodology for deriving the probabilities of default (PDs) of CCP clearing members which will be used by ESMA to define their default scenarios.

The scenarios cover an assumed, abrupt materialisation of one or multiple risks to the EU financial system as identified by the ESRB. The materialisation of these risks would unfold in a weak macroeconomic environment characterised by subdued nominal growth, by banks in various EU Member States facing high levels of non-performing loans, and by continued low interest rates that put downward pressure on banks' profitability. The risks that may materialise and have adverse consequences in such an environment include a repricing of global risk or a reversal of risk premia and related price adjustments reflecting a possible rise in concerns over public debt sustainability. Moreover, stress could arise in the investment fund sector and amplify liquidity risks and spillovers to the broader financial sector. For the purposes of designing suitable scenarios to stress test CCPs, it is important to note that these risks could materialise jointly and reinforce each other.

¹ The scenarios have been designed using a nonparametric conditional expected shortfall technique. This tool, which is part of the suite of stress test models used by the ECB's Directorate General Macroprudential Policy and Financial Stability, is described in more detail in Box 2 of the adverse scenario provided for the 2015 EIOPA EU-wide pension fund stress test (see <https://eiopa.europa.eu/Publications/Surveys/ESRB-2015-03-20%20GB%202011%20%20EIOPA%20%20pension%20fund%20ST%20after%20ESRB%20GB.pdf>).

Narrative of the CCP stress test scenarios

The scenarios for the CCP stress test take as a starting point the materialisation of any of the key risks to the EU financial system identified by the ESRB. This could happen in the event that new information or data is released that hints at a likely or actual materialisation of one or more of these risks. This, in turn, may result in a surge in risk premia, leading to major shifts in market prices across a broad range of asset classes. In such an event, market price movements would be coupled with increased volatility. The dependence between asset prices observed during normal times would likely change materially during a short period of time, with no clear direction of safe-haven flows across countries and markets. While such unprecedented asset price movements may be short-lived and global financial markets may stabilise swiftly, it is assumed that markets would undergo pronounced stress lasting for at least five days.

Calibration of the scenario

The scenarios are designed to ensure that CCPs clearing a wide range of financial products are subjected to sufficient stress. To achieve this, three adverse scenarios have been designed. They differ from each other with respect to the market segment in which a shock is assumed to originate. Each scenario is consistent in that historical dependencies of all risk factors vis-à-vis the shock origin are accounted for. Table 1 provides an overview of the scenarios and Annex B provides details of the individual risk factors.

In the CDS spread shock scenario, the set of risk factors that are shocked consists of six underlying iTraxx indices comprising European sovereigns and financial and non-financial corporations. The FX scenario uses the exchange rates of the euro vis-à-vis a subset of major currencies (Swiss franc, Chinese renminbi, pound sterling, Japanese yen, US dollar, Australian dollar and Canadian dollar). In this scenario a negative shock means a depreciation of the euro. Finally, the interest rate scenario assumes an onset of turbulence in money markets, which is reflected by considering a shock to the euro swap rate curve.

Table 1: Scenarios – shock origins and shock directions

#	Description	Acronym	Shock direction
1	CDS markets	CDS	+
2	Foreign exchange markets	FX	-
3	Money market and swap rates	RATES	+

The scenarios are derived using a two-step procedure. In a first step, a nonparametric conditional expected shortfall shock simulation is conducted using a rolling window of 60 business days over a sample period from January 1990 to September 2016. This step produces for each 60-day window the responses of individual risk factors conditional on the specific variables used as the shock origin. In a second step, for each scenario the 60-day

window which, on average, implies the maximum conditional responses to the shock is selected to produce the scenario shock responses.

Overview of the scenario results

Table 2 presents the median responses of risk factors to the shock for each of the three scenarios across seven different market segments and using a two-day or a five-day forward horizon.² Overall, the responses are largest for the segments with variables that co-move with the variables used as the shock origins. The shocks for this exercise are generally smaller than those used in the 2016 bottom-up stress-test, which were not calibrated consistently across variables. However, for many of the risk factors, the responses to the shock are close to the historical two-day minimum or maximum shifts in risk factors. To recall, following the default of a clearing member, a CCP needs to be able to withstand adverse price changes for a minimum of two to five days to close out positions.

Table 2: Scenarios – median responses

Market segments	Segment	Type	Units	Scenarios		
				CDS	FX	RATES
Equities	Price	percent	-16.1	-7.7	-8.0	
	Volatility	multiple	1.29	1.09	1.08	
Commodities	Price	percent	-8.9	-1.9	-2.8	
	Volatility	multiple	1.03	1.04	1.00	
Sovereign bonds	Yield 1Y	bps	9	4	18	
	Yield 5Y	bps	42	11	24	
	Yield 10Y	bps	45	21	42	
	Yield 30Y	bps	28	26	45	
FX	Price	percent	-2.8	-5.7	-4.5	
	Volatility	multiple	1.29	1.03	1.00	
CDS	Indices	multiple	1.45	1.27	1.22	
	Sectors	multiple	1.53	1.21	1.44	
Rates	OIS rates	bps	-5	1	3	
	Other Rates	bps	14	3	10	
	Volatility	multiple	1.10	1.01	1.02	
Corporate bonds	Yield uncovered bonds	bps	64	26	61	
	Yield covered bonds	bps	46	22	54	

Note: For volatility shocks, a “multiple” is a factor that will be applied to volatility starting points as observed at a reference date. For the CDS segment, “indices” refers to a set of underlying iTraxx indices and “sectors” refers to various underlying industries.

² See the accompanying tables (Annex B) for the detailed shock profiles for all individual risk factors. CDS, FX, and RATES scenarios are generated using a two-day simulation horizon. In addition, the CDS and RATES scenarios are scaled up to a five-day horizon. These horizons were chosen in order to align the magnitude of the shocks with episodes of market stress in the past.

Annex A: Methodology for designing scenarios for ESMA's EU-wide CCP stress test

1. Methodology

1.1 Risk factor coverage

Each scenario calibrated by ECB staff includes more than 500 risk factors.³ These risk factors cover seven segments: (i) equity markets (ii) commodity markets, (iii) sovereign bond markets, (iv) foreign exchange markets, (v) CDS markets, (vi) money markets, and (vii) corporate bond markets. The database contains prices, yields, and implied volatilities. The sample period for all risk factors includes daily data from 4 January 1999 to 16 September 2016 (about 7,000 time series observations). Each of the consistent scenarios originates from a set of shocks to particular variables from which the responses of all other risk factors across segments are derived.

1.2 Simulation methodology

The simulation methodology is based on a nonparametric conditional expected shortfall approach. In each of the scenarios, the shock originates in a market segment to which CCPs are exposed. The dependencies of all risk factors vis-à-vis the shock origin are captured in a nonparametric manner, i.e. without pre-imposing any parametric functional form on either the marginal distributions or the copula that, together, constitute a joint distribution of all factors. Many of the factors involved in the scenarios are characterised by highly non-normal features; therefore, a nonparametric approach is warranted in order to avoid parametric misspecification that might otherwise result in an underestimation of tail risk responses.

The scenarios are designed under the assumption of a predefined shock probability of 0.1%, along with a forward horizon of two or five business days.⁴ First, a nonparametric conditional expected shortfall shock simulation is conducted using a rolling window of 60 business days over the whole sample period and the conditional responses of all risk factors are recorded. Then, in a second step, the 60-day window which, on average, implies the maximum conditional responses to the shock is selected to generate the shock responses.

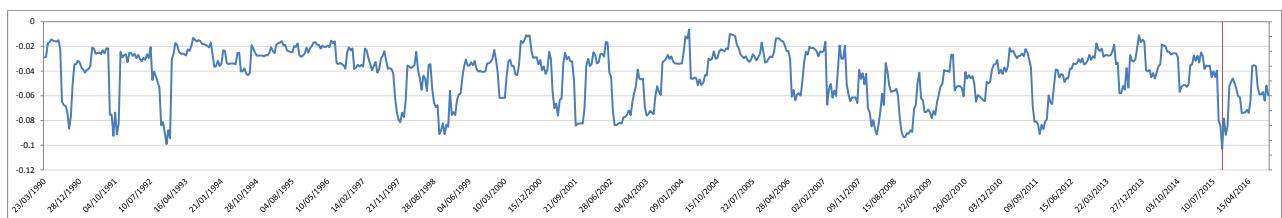

To illustrate the window selection step, Chart A1 shows the evolution of the average response of 15 different sector-specific equity market indices, with the bank equity index used as the shock origin. Each point in the chart corresponds to the end of a 60-day window. As an example, the maximum negative response of equity market index returns to a shock to the

³ While the scenarios were calibrated using 1075 individual risk factors, Annex B reports 553 risk factors for each scenario. This reflects aggregation and, in particular, money market rates and volatility shocks being reported only for selected tenors. Sector level CDS shocks were reported as a 90th percentile over the single name CDS shocks/responses corresponding to the various sectors.

⁴ Under the plain bootstrap approach, used in these simulations, it was not possible to achieve higher severity over a two-day horizon, as reducing the probability to below 0.1% did not add to the severity for statistical reasons. Therefore, the shock response profiles were initially simulated at the two-day horizon with a 0.1% probability and then scaled up to a five-day horizon for CDS and RATES scenarios in order to achieve higher severity.

bank equity price return can be found when referring to the 60-day window spanning the period August to September 2015.

Chart A1. Average equity market index returns following a shock to bank equity returns based on a 60-day moving window

This window selection approach is employed for all seven market segments and across the three scenarios.

Annex C: Methodology for quantifying PDs for ESMA's default scenarios

There are two approaches to quantify probabilities of default (PDs). First, CDS spreads can be used to infer annual PDs (five-year CDSs were used as they are the most liquid). Second, actual – or “real world” – PDs from Merton-type models can be used. Both approaches have advantages and disadvantages.

While CDS-implied PDs are available for a large number of institutions, they are not a reliable measure of actual probability of default. CDS-implied PDs have the following advantages: i) they can easily be computed from observed CDS spreads, without any further data being required and; ii) they can be obtained for a comprehensive list of institutions, as CDSs are often traded for institutions without traded equity. The disadvantages/caveats are: (i) that CDS spreads, and hence the implied PDs, include a premium that reflects investor risk aversion and which leads to an upward bias relative to actual PDs; this premium is likely to be time varying, which further complicates the interpretation of changes in CDS-implied PDs over time; and (ii) they can be contaminated by implicit or explicit government guarantees. This is a concern in particular for large institutions, whose CDS-implied PDs would for that reason be expected to be downward-biased.

PDs inferred from Merton-type models are a more reliable measure of actual PDs. Their advantages mirror the CDS-implied PDs’ disadvantages, i.e. they should not be contaminated by guarantees or risk premia. Their main disadvantage is that they are available for a smaller number of institutions as their computation requires reliable balance sheet and equity price data. Given this practical disadvantage, the PDs that will be provided for ESMA's default scenarios will be based on CDSs.

Computation of CDS-implied PDs

The following formula is used to compute CDS-implied PDs data from five-year CDS spreads

$$CDS - \text{implied PD} \cong 1 - e^{-\left(\frac{CDS}{LGD}\right) \times \left(\frac{T}{10000}\right)}$$

where T denotes the maturity of the CDS and LGD the loss given default of the clearing members. Since five-year CDS spreads are used, T is set equal to 5, in order to obtain PDs with a one-year horizon. A uniform LGD of 80% will be assumed.⁵

⁵ Neither the assumption about the level of the LGD nor the scaling to a one-year horizon via the parameter T have an effect on the ranking of clearing members resulting from the CDS-implied PDs.
